Towards Effective and Efficient Identification of Potential Tax Agent Compliance Risk: A Stratified Random Sampling Approach

Ying Yang, Esther Ge, Ross Barns

Abstract

We propose to use a stratified random sampling approachentifydwhether a tax agent's return preparation behaviour is significantly different from its industry norm. Given a tax agent's our approach creates a istitucally sufficient number of notional peers for it. These peers comprise a reference group form the expectation for A's tax return behaviour can be derived there from. By comparing A's actual behaviour agent its expected behaviour, one can infer whether behaves abnormally and to what degree T A incurs potential pliance risk. The novelty and advantage of our approach includes (1) effective and efficient risk entification, (2) an easy-to-understand thodology, (3) easy-to-explain results), (no need for any pre-defined threshold values and hence less to abbe undermined by "game players" who seek to make claims just under the threshold, and (5) low cost of ideatific as our approach conducts supervised learning that does not demand a supply of labelled tax age at straining data.

1. Introduction

Individual income tax is a major revenseurce for the Australian government. Over

A definitive solution to tax agent complianer risk identification is to check every single tax return lodged by every single agent and then reach a conclusive statement. However such a solution is neithractical nor sustainable due to resource

2. How to Create Peers for a Tax Agent

Given a tax agent T A, our approach creates a statistically sufficient number of peers for T A. These peers compe a reference group (the industry norm) against which T A is compared. This section first introduce the finition of a peer and then proposes how to create peers.

2.1 Definition of a peer

For a tax agent T A, a peer need satisfy the following two criteria.

(a)

(3)

3. HOW TO EVALUATE A TAX AGENT'S POTENTIAL COMPLIANCE RISK

We evaluate an actual tax agent T A'teptial compliance risk by comparing T A against its notional peers.

3.1 The normal distribution

Since T A's peers are created by randsampling with replacement and with stratification according to T A's rental properties' postcodes, all the peers are equal-size random samples from the same population.

3.3 The risk score

The risk score combines both the risk wolderreporting rental gross income (z-score(income)) and the risk of overclaiminental gross expense (z-score(expense)). Because a z-score is a standardised valuectal culates how many counts of standard deviations the actual value of a tax agrails away from the average value of its peers, z-score(income) and z-score(expense) are commensurate and hence we can apply mathematical operations on themcalculate the risk score. For T A we can calculate its z-score of rental gross incorescore(income), as well as its z-score of rental expense, z-score(expense). The lathwervalue of z-score(income), the less the rental gross income declared by T A this peers, and hence the higher the possible

- x Peers' maximum \$ value per property: the biggest mean rental gross income or expense value among all the peers.
- x Peers' standard deviation: the standard into of the peers' mean rental gross income or expense values.
- x z-score: the standardised difference been the tax agent's actual rental value and its expected value drawn from its peers.
- x Risk score = z-score(gross expensæ)score(gross income). It is used to rank actual tax agents in terms of compliance risk. The higher the risk score, the higher the potential compliance risk.
- x Risk rank: this tax agent's rank amonty actual tax agents in terms of

(a) Rental gross income

(b) Rental gross income

FIGURE 3: Compare Tax Agent X's mean rental gross income and mean rental gross expense respectively against its peers'. X underreportsits rental income but overclaims its rental expense.

Thus, Tax Agent X underreports its rentatione but overclaims its rental expense. Overall it incurs a risk score of 22.99 (=21.21-(-1.78)), which is the highest among

FIGURE 5: Individual tax agents' risk scores for a tax return year.

4.3 Effciency

Our proposed stratified random sampling algorithm is very efficient. Given the rental

possesses potential compliance risk. But there can be many reasons behind such a symptom. Possibly Tax Agent X correctly reports gross income but significantly overclaims gross expense; or possibity correctly claims gross expense but significantly underreports gross income; or possibly it both underreports gross income and overclaims gross expense. Howeveranalysis of net income alone would not reveal these useful details.

FIGURE 7: Compare Tax Agent X's mean rental net income against its peers'.

Alternatively one can use behaviours modetailed than gross income and gross expense. For instance, gross expense caurather divided into expenses of bank loan interest, capital works and other expenses.

Risk score =
$$-z(gross income)$$
 (3)

Note that \$(gross expense) = \$(bank limiterest) + \$(capital works) + \$(other expenses). However, z(gross expenses) bank loan interest) + z(capital works) + z(other expenses) because a z-scores is and ardised value. Instead 3xz(gross expense) \$z(rental interest) + z(capital works) + z(other expenses).

5.2 The central limit theorem

According to Moore [5], the central limit the mean says that the distribution of a sum or average of many small random quantities is

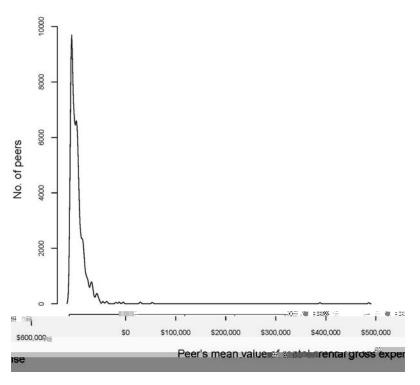

FIGURE 8: A small tax agent has only one rental preperty. Its peer means does not follow a normal distribution.

5.3 Median vs. mean

Sometimes people are interested in a tax tax median rental value instead of its mean rental value Extra cautions are required when applying our stratified random sampling approach to compare a tax agenetian value against its peers'. Although it applies to the mean statistic, the centimal theorem does not necessarily apply to the median statistic. That is, the peers diame rental values do not necessarily follow a normal distribution. For instance, as illustrated Figure 9(a) the median rental gross income values of Tax Agent Y's peers asseua bimodal distribution instead. As a result, a z-score is not always applicabled we cannot use Formula (2) to calculate the risk score. Nonetheless, it happens in tax is case that the median rental net income values of Tax Agent Y's peers stillow a normal distribution as depicted in Figure 9(b). Thus it is acceptable for one to

(a) For Tax Agent Y, the peers' mediantures of rental gross income follow a bimodal distribution instead of a normal distribution. Hence a z-score is not applicable.

(b) For Tax Agent Y, the peers' mediarhuess of rental net income do follow a normal distribution. Hence a z-score is applicable.

FIGURE 9: The central limit theorem does not cover the median statistic. If using median instead of mean to measure tax agent behaviour, one should always check whether peer median values follows a normal distribution before adopting the z-score to quantify a tax agent's potential compliance risk.

5.4 Ratio

In general, we discourage using ratio values as behaviour, such as . It is because a small denominator value will blow

up the ratio and distort the behaviour. Theremae is when denominator is 0 and the ratio becomes infinitely big. Even if weeplace 0 with some positive value to solve the infinity problem, the distortion problem still exists. Table 3 shows a true story. Tax Agent Z has 18 rental properties, whose rental gross income and gross expense are listed in Table 3. 10 out of the 18 properties have \$0 gross income. In order to

x Risk rank = 1.

Thus Tax Agent Z incurs a very high risk score of 979.81 and is ranked as top risk, whereas the second highest risk score ambrigaagents is only 33.33. We suggest that Tax Agent Z's risk is largely exaggedated ratio is the reason to the distortion. Hence one needs to be very cautious when using ratio.

6. RELATED WORK

Our concept of "notional peers" is inspired by Bloomquist, Albert and Edgerton's bootstrap approach to evaluating preparation accuracy of tax agents [1]. In Bloomquist etc.'s study the tax agent behaviour is Albert discrepancy rate, which equals to the number of tax returns lodged by a tax agent with potential misreported values divided by the total number of tax returns lodged by that tax agent. The misreported errors of tax returns are identified by the Automattenderreporter (AUR) program of the US Internal Revenue Service. Assume a tax returns of Postcode 20134 and 45 tax returns of Postcode 20143. The bootstrap approach creates T A's notional peers and evaluate T A's cotiampce risk by the following steps.

- Step 1: Randomly pick 12 and 45 tax resumom all the tax returns of Postcode 20134 and Postcode 20143 respectively resulting 57 (= 12 + 45) picked tax returns will contribute to create a notional peer Peer1 for T A as in Step 2.
- Step 2: For each of the above 57 tax returns, a uniform random number(0) is generated. If the value of u is less than or equal to the AUR discrepancy rate of the tax return's corresponding Postcode, a value 1 is added into Peer1's base; otherwise, a value 0 is added into Peer1's base.
- Step 3: Compute Peer1's AUR discrepancy rate as where {0, 1}.
- Step 4: Repeat Steps 1-3 for 1000 tinges ating 1000 notional peers for T A. The expected AUR discrepancy rate fo ATequals to the average value of the 1000 notional peers' AUR discrepancy rates:
- Step 5: Obtain the one-tailed 95% confiderinterval by sorting the 1000 peer AUR discrepancy rates in ascending order and selecting the cutoff as the 950th value.
- Step 6: If T A's AUR discrepancy rate ceeds the 95% confidence interval (the 950th value), it is identified as being a potential risk.

We respectfully suggest that the boratest approach does not quantify tax agent compliance risk. Consequently, it does not pare risk degrees across different tax agents to offer a risk ranking among multiple tax agents. However a proper risk ranking is highly desired in tax administrom organisations such as the Australian Taxation Office because it enhances the differences and efficiency of tax audit under resource constraints. Hence we have instead proposed a stratified random sampling approach where we have proved via the definition theorem that one can use the z-score to quantify potential tax agent risagarding a behaviour. Meanwhile, since z-

scores are commensurate across different behaviours, we can apply mathematical operations on them to calculate a collectivisk score for each tax agent. Multiple agents can be ranked according to thesik scores. These scores together with our proposed descriptive illustrations can provideportant insight into the integrity an compliance level of a single tax agent as well as of the whole tax agent industry. Hsu etc. reported to use supervised learning to rove the audit selection procedure at the Minnesota Department of Revenue [3].the machine learning and data mining fields of computer science, there exist supported learning versus unsupervised learning approaches [4, 6]. Supervised learning setedining data, that is, an unbiased and representative sample of the whole populationere each of the sample returns has a known outcome (compliance or noncompliance). From the training data supervised learning infers a classifier to differentiate between compliance and non-compliance tax returns. This classifier is then used transify other unlabelled tax returns. In their particular work, Hsu etc. had access to neaturns with auditing results and trained a naive Bayes classifier therefrom. In contrast, we lack the luxury of having good training data of agent compliance risk duethe fact that tax agent client bases are immensely diversified. Thus our proposee proach is unsupervised learning that does not demand a supply of labelladents. As a result, our approach is of very low cost and can be easily made operational. A tradial risk identification approach in the Australian Taxation Offce is to use business expert rules. A rule system often first specifies non-compliance patterns accordingdomain experts' previous experience,

normal distribution. Therefore one can use th
